1 Introduction

For the project in High Performance Programming I chose to implement parallel bucket sorting in c. I did this using OpenMP since it is more straightforward than Pthreads, and since micromanaging threads will likely not be necessary for this problem.

2 Problem

Bucket sort is a sorting method that works by dividing the list into multiple sublists or "buckets". The division of the original list is done by element size, which means the list is partially sorted after the elements have been distributed to the buckets. Then each bucket is sorted locally using a sorting method of choice, after which the elements in the buckets are put back into the original list in order resulting in a sorted list. The method can be broken down into four main steps:

- Bucket creation.
- Bucket distribution.
- Local bucket sorting.
- List redistribution.

The most time-consuming step is the local bucket sorting, which is why it is the main step to parallelize. The other parts are less computationally demanding but can also be coded to run in parallel to gain some performance. The project also includes implementing three different types of value distribution for the list; uniform, normal and exponential.

3 Solution

3.1 Algorithm

3.1.1 Bucket creation

The buckets were implemented using a 2D array. First memory was allocated for an int**-array of length equal to number of buckets, which will act as a cointainer for the buckets. For each element in the bucket container, memory was then allocated for an array of integers. These arrays will act as the actual buckets. The length of the allocated buckets was set equal to the size of the original list, this is however a subject of optimization since it requires alot of memory.

3.1.2 Bucket distribution

In order to sort the elements into its correct bucket, some hash function was needed that takes the element value and returns a bucket index. There are several ways to do this and it is a key piece in managing the work load balance for the parallelization. Ideally every bucket receives the same number of elements, however the distribution of list values plays a big role here. An algorithm that works well for uniformly distributed values might not work well for normal or exponentially distributed values and vice versa.

The chosen algorithm works by assigning each bucket a value interval and then distributing list elements accordingly. This works best for uniformly distributed lists. First the range of values in the list is found by taking the difference between the minimum value and the maximum value. The bucket index for a list element is then calculated by the following formula:

Bucket Index =
$$floor((element value - min value) \cdot \frac{Number of buckets}{list range + 1})$$
 (1)

This is done in a for-loop for every list element. To avoid repeated double division, which is computationally intensive, the fraction part is calculated beforehand so that only subtraction and multiplication is done inside the loop.

3.1.3 Local bucket sorting

After the buckets have recieved their elements, it is time to sort them locally. This can be done using any sorting method, including recursive bucket sort. Since this is the part that should be the most time consuming, the choice of sorting method is essential for overall performance. The easiest choice is insertion sort, which is efficient for short lists but is very time-consuming for large lists as it scales with $\mathcal{O}(n^2)$ on average. For longer lists it would be better to use something like quicksort, however quicksort would be slower than insertion sort for small lists as it requires more overhead. In this implementation insertion sort was initially chosen as method, but combining this with quicksort for longer lists would improve performance and is an option for optimisation.

3.1.4 List redistributing

This part works by nesting two for-loops, one for looping through the buckets in order and a second one for looping through the bucket elements. Each element is inserted into the original list at a position determined by an loop-independent index variable that is incremented with each insertion.

3.2 List generating

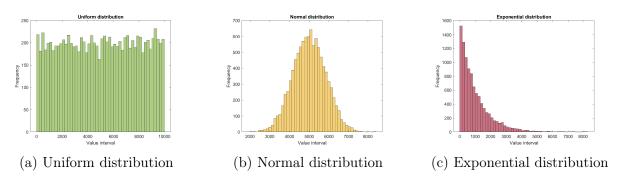

Figure 1: Different distributions for a list of size N = 10~000

3.2.1 Uniform distribution

To achive uniform distribution each element in the list was set to a random value between 0 and N, where N is the length of the list. This range was chosen to avoid an abundance of repeated numbers in the list.

3.2.2 Normal distribution

To achive normal distribution each element in the list was set to a a value generated by a Box-Muller transform. Firstly two variables, u and v, are created and given random values between 0 and 1. Another variable z is then calculated using the following formula:

$$z = \sqrt{-2 \cdot \ln(u)} \cdot \cos(2\pi \cdot v) \tag{2}$$

This variable can be interpreted as the amount of standard deviations σ the number will deviate from the mean μ . Finally the list element is set to $z \cdot \sigma + \mu$, and the process is repeated for all elements. The shape of the generated bell curve will depend on the choice of μ and σ . In this project the values were set to $\mu = N/2$ and $\sigma = N/12$ for a list of length N, which resulted in a good looking curve.

3.2.3 Exponential distribution

To achive exponential distribution each element in the list was set to a value given by the inverse transformation method. The method works by calculating the inverse of the cumulative probability function, and then submitting a uniformly random number between 0 and 1 as parameter.

$$F(x) = 1 - e^{-\lambda x} \to F^{-1}(x) = -\frac{\ln(1-x)}{\lambda} \to \text{value} = F^{-1}(u), u \in [0,1]$$
 (3)

The range of the distribution curve is decided by the value of λ , which in this case is set to 0.001.

3.3 Optimization

The code was at first optimised for serial execution, as this should mostly carry over to parallel execution.

3.3.1 Number of buckets

It was presumed that the number of buckets should scale with the size of the input list, therefore some different list sizes combined with different number of buckets were tested:

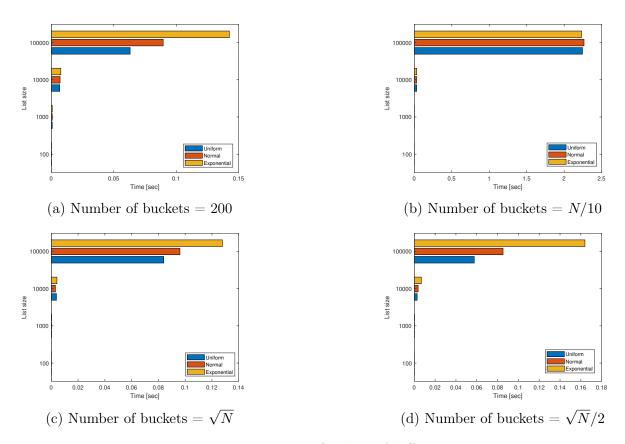

Figure 2: Execution time for lists of different sizes N

It is visible in Figure 2 that the overall best performance was achieved with number of buckets being set to $\frac{1}{2}\sqrt{N}$ (Figure 2d), and the worst performance with number of buckets being a tenth of the list size. From this it can be deduced that a relatively small amount of buckets in comparison to the list size is preferable. It is also a clear trend that the exponential distribution results in worse performance. This is expected since the work load between buckets wont be even, and insertion sort will have to sort bigger lists than desired.

3.3.2 Work load balance

The part that is the most time-consuming is the local sorting of the buckets, which is why it is desirable to do so in parallel. The parallelization will however be held back by the number of elements in the buckets. If one bucket contains half the lists elements the parallelization will not improve performance as much as it could since the work balance is uneven.

The first implementation of the distribution algorithm works by finding even size intervals from the range of list element values. This results in good distribution and work balance if the list elements are uniformly distributed, since every bucket will contain roughly the same amount of elements. If the list elements are subject to normal or exponetial distribution this is not the case, and finding a way to achive this would improve overall performance greatly.

Ideally there would exist a hash function that evenly sort the datapoint into the buckets, no matter the distribution of the datapoint values. However no such function exists that is computationally cheap enough, and changing the hashing function according to the distribution of data given by the user is unrealistic. Instead the code can be altered to better handle the buckets with many elements. One way of accomplishing is by implementing quicksort and use it instead of insertion sort for bigger buckets. Insertion sort is still faster than quicksort for some small lists sinice it requires less overhead, hence the bucket length needs to be compared to some factor in order to decide which sorting method to use. After testing it was discovered that insertion sort performed better on lists under the length of 10, which was then chosen as factor.

After implementing quicksort the performance compared to only insertion sort improved as follows:

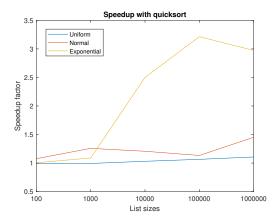

Figure 3: Speedup for list sizes N after implementing quicksort. Buckets = $\sqrt{N}/2$

As expected the exponentially distributed lists were affected to most by the implementation of quicksort, with a speedup factor over 3.0 for longer lists. Lists with uniform and normal distributed were affected less but still gained performance, and there is a visible trend that normal distribution lists will gain more speedup for even longer lists.

3.3.3 Bucket creation

After implementing quicksort the local bucket sorting is no longer the most time-consuming step. With a list size of 1 000 000 almost all time was spent on creating buckets and allocating memory:

	Uniform	Normal	Exponential
Total time [s]:	1.124530	1.138399	1.471471
Bucket creation [s]:	1.099310	1.102726	1.102399
Percentage:	97.7%	96.8%	74.9%

Table 1: Time for memory allocation using only malloc(). List size $N=1\ 000\ 000$

Optimising this part is a ket step in improving performance. Before improvement the code function as follows:

```
int **buckets = malloc(N_buckets*sizeof(*buckets));
int *bucket_count = malloc(N_buckets*sizeof(*bucket_count));
for(int i = 0; i < N_buckets; i++){
    buckets[i] = malloc(N_list*sizeof(*list));
    for (int j = 0; j < N_list; j++){
        buckets[i][j] = 0;
    }
    bucket_count[i] = 0;
}</pre>
```

First, memory for each list is allocated using malloc(). Then each element in the 2D buckets-array and the regular bucket_count-array is initialized to 0 using a nested for-loop. The two for-loops are likely the time-consuming part, and they can be replaced to improve performance. Instead of allocating space using malloc(), calloc() can be used to allocate memory and initialize to 0 at once. This means the nested loops can be replaced with only one loop over each bucket. Additionally, the individual bucket elements do not need to be intialised at all:

```
int **buckets = malloc(N_buckets*sizeof(*buckets));
int *bucket_count = calloc(N_buckets, sizeof(*bucket_count));
for(int i = 0; i < N_buckets; i++){
    buckets[i] = malloc(N_list*sizeof(*list));
}</pre>
```

	Uniform	Normal	Exponential
Total time [s]:	0.026911		0.379130
Bucket creation [s]:	0.002262	0.002288	0.002251
Percentage:	8.4%	6.0%	0.6%

Table 2: Time for memory allocation using calloc(). List size N = 1~000~000

It is visible in Table 2 that memory allocation is now only a small part of the entire process. This optimisation was clearly a huge improvement for performance.

3.3.4 Memory optmisation

As seen in the bucket creation optimisation, memory is allocated for each bucket to fit the entire list. This is in the event of the worst case scenario where almost every element would be put into one bucket. Obviously it is impossible for the entire list to be put into every bucket, meaning this is a huge waste of memory. Instead the array bucket_count can be used to determine how many elements are going into each bucket before allocating the necessary memory. This means a new for-loop needs to be added which will increase execution time, but sacrificing some time to gain a big improvement in memory efficiency is probably a good trade-off.

Total memory allocation can be displayed using valgrind. For a list of size $N=1\,000\,000$, the following improvement was recorded:

	Before:	After:
Time [s]:	0.028510	0.024869
Total allocation:	$\sim 2 \text{ Gb}$	~8 Mb

Table 3: Time and total allocation, list size N = 1~000~000, Number of buckets $= \sqrt{N}/2$.

In Table 3 it is clear that the change resulted in a huge improvement regarding memory allocation. This was expected and makes sense when looking at the math. Before optimisation each bucket was given memory for the entire list. With 500 buckets and a list of one million integers the memory allocation can be calculated as:

Memory = 4 bytes
$$\cdot 1000000 \cdot 500 = 2000000000$$
 bytes = 2 Gb (4)

With the new algorithm the total memory for all buckets will equal the list, so only twice the list size will be allocated in total:

Memory = 4 bytes
$$\cdot 1000000 \cdot 2 = 8000000$$
 bytes = 8 Mb (5)

This matches the information in Table 3. Hower, Table 3 also shows that the total time is lower, which means the time for the additional for-loop is less than allocating all the extra memory.

3.4 Parallelization

3.4.1 Local bucket sorting

The main step to parallelize is the sorting step. Since it is just a for-loop that iterates over the buckets and calls a sorting function, it can easily be parallelized using #pragma omp parallel for. If the list is uniformly distributed, the work load will be even between threads without having to change the schedule() method. Since every bucket will be of almost equal length the default static scheduling will give each thread almost equal work. However with normal or exponential distribution the work load will be very unbalanced. With normal distribution the middle threads will have to sort the majority of the list, while the beginning and end threads will have very little work. Because of this, setting it to schedule(dynamic) makes sense. This will assign the threads more work as they finish their iteration, ensuring better work balance than before at the cost of

some additional overhead. The parallelization of the local bucket sorting resulted in the following improvement:

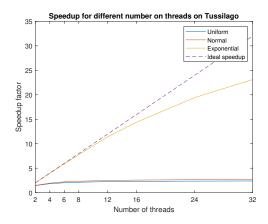

Figure 4: Speedup for different number of threads. N = 10^7 , Buckets = $\sqrt{N}/2$

The speedup it not close to ideal, except for lists with exponential distribution. This is because only the local bucket sorting is parallelized, the other parts of the method are still run in serial. The time consumption for these parts is independent of distribution type, and since exponential list take significantly longer to sort they appear to follow the ideal speed up since the local sorting time dominates. To observe the effect of parallelization the time for the local bucket sorting can be plotted instead:

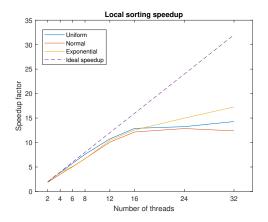

Figure 5: Speedup for local sort, $N = 10^7$

It is visible in Figure 5 that the sorting for all three distribution roughly follow the ideal speedup up to 16 threads, after which the speedup curves flatten out. In order to improve the total speedup, the other parts have to be parallelized as well.

3.4.2 Bucket creation and distribution

To parallelize the bucket creation and distribution it has to be mostly rewritten. As described in Section 3.3.3, the algorithm functions by first looping through the list to find some necessary values:

```
int max_element = list[0], min_element = list[0];
for(int i = 1; i < N_list; i++){
    if(list[i] > max_element) max_element = list[i];
    else if(list[i] < min_element) min_element = list[i];
}
int range = (max_element - min_element);
double temp = (double)N_buckets/(range+1);</pre>
```

Afterwards there is a second loop for memory optmisation, and some allocation:

```
for (int i = 0; i < N_list; i++){
    int bucket_index = (int)((list[i]-min_element)*temp);
    bucket_count[bucket_index]++;
}

for(int i = 0; i < N_buckets; i++){
    buckets[i] = malloc(bucket_count[i]*sizeof(*list));
    bucket_count[i] = 0; //reset bucket count
}</pre>
```

Finally the elements are distributed with a third loop:

```
for (int i = 0; i < N_list; i++){
   int bucket_index = (int)((list[i]-min_element)*temp);
   buckets[bucket_index][bucket_count[bucket_index]] = list[i];
   bucket_count[bucket_index]++;
}</pre>
```

To find the arrays maximum and minimum values in parallel, a reduction clause in OpenMP can be used. For this only one line needs to be added above the for-loop:

```
#pragma omp parallel for reduction(max:max_element) reduction(min:
min_element)
```

The rest of the loops are not parallelizable as the position of each element in its bucket is dependent on a variable which is incremented with each iteration. In order to parallelize these, the code has to be rewritten. First an additional array is created of the same length as the list. This is for storing each list elements corresponding position in the bucket, which was previously done by incrementing the bucket_count-array.

```
int *list_element_bucket_count = malloc(N_list * sizeof(*list));
```

Now an iteration over the list is required to fill the new array with values:

```
int bucket_index;
for (int i = 0; i < N_list; i++){
    bucket_index = (int)((list[i]-min_element)*temp);
    list_element_bucket_count[i] = bucket_count[bucket_index];
    bucket_count[bucket_index]++;
}</pre>
```

The addition of this arrray means that each list elements position in its bucket is already known, making the loop iterations independent and parallelizable:

```
#pragma omp parallel for
for(int i = 0; i < N_buckets; i++){
    buckets[i] = malloc(bucket_count[i]*sizeof(*list));
}

#pragma omp parallel for
for (int i = 0; i < N_list; i++){
    bucket_index = (int)((list[i]-min_element)*temp);
    buckets[bucket_index][list_element_bucket_count[i]] = list[i];
}

//this is no longer needed
free(list_element_bucket_count);</pre>
```

This solution is a bit more memory expensive, as additional memory equal to the list size is allocated. However this is significantly less than was saved with the memory optimisation in Section 3.3.3. After this implementation the following time improvement for was recorded:

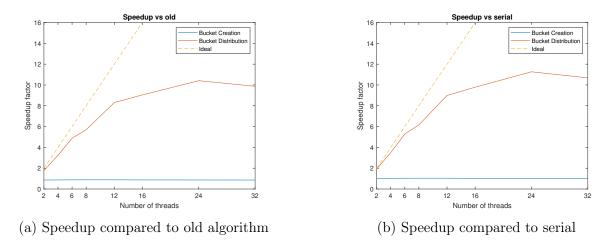

Figure 6: Speedup with new bucket algorithm, $N = 10^7$

As seen in figure 8 the bucket distribution is up to ten times faster than the old algorithm and up to 12 times faster than serial, when using 24 threads. It also follows ideal speedup behaviour fairly well up until 12 threads. The bucket creation does not not speed up which is expected since it was not parallelized.

3.4.3 Bucket resdistribution

The last part to parallelize is putting back the elements from each bucket into the list. This is not very time-consuming but could be still be improved slightly. It was previously done by two nested for-loops iterating through each bucket and each elements. In the inner loops a variable keeping track of the index in the list is incremented.

```
int list_index = 0;
for (int i = 0; i < N_buckets; i++){
    for (int j = 0; j < bucket_count[i]; j++){
        list[list_index] = buckets[i][j];
        list_index++;
}</pre>
```

To parallelize this the list_index variable needs to be removed since it would make the iterations independent of each other. Each elements posisition in the list can instead be calculated using the cumulative sum of the bucket_count-array with the following formula:

```
index = bucket\_count[0] + bucket\_count[1] + ... + bucket\_count[i-1] + j (6)
```

This would give the correct index in the list for an element at position j in bucket i. To implement this another array is required of the same size as bucket_count, which will hold the cumulative sum of all previous buckets:

```
int *bucket_accum = malloc((N_buckets)*sizeof(*bucket_accum));
bucket_accum[0] = 0;
for(int i = 1; i<N_buckets; i++){
    bucket_accum[i] = bucket_count[i-1] + bucket_accum[i-1];
}</pre>
```

If the list index is calculated this way the for-loop is perfectly parallelizable, giving the following results:

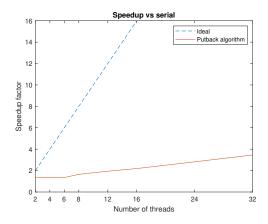

Figure 7: Speedup for putback using cumulative sum, $N = 10^7$

It is clear in Figure 7 that the change did not have a big impact, as the time consumption was already small and the speedup factor only reaches four.

4 Experiments

4.1 Timing for different N's

The following timings were made on the linux server vit sippa.it.uu.se using 32 threads. Number of buckets used was $\frac{1}{2}\sqrt{N}$ for each list size N.

List size:	1 000 000	10 000 000	100 000 000	1 000 000 000
Total time [s]:	0.025	0.230	2.447	32.522
Bucket creation time [s]:	0.020	0.178	1.837	23.808

Table 4: Timings for uniform distribution

List size:	1 000 000	10 000 000	100 000 000	1 000 000 000
Total time [s]:	0.028	0.236	2.550	31.274
Bucket creation time [s]:	0.020	0.175	1.769	20.077

Table 5: Timings for normal distribution

List size:	1 000 000	10 000 000	100 000 000	1 000 000 000
Total time [s]:	0.069	4.178	330.506	-
Bucket creation time [s]:	0.019	0.174	2.253	-

Table 6: Timings for exponential distribution

Final speedup factors, run on arrhenius.it.uu.se which has 16 available threads:

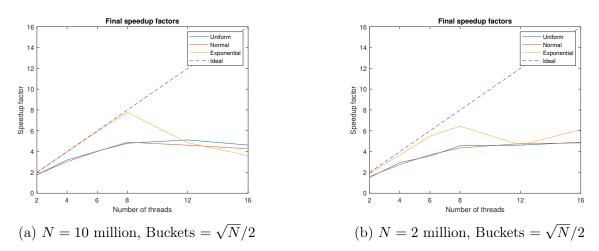

Figure 8: Final speedup factors on arrhenius serever

5 Discussion and conclusions

After running tests for different large list sizes, as seen in Section 4, it is clear that the bucket creation loop that is introduced in the optimisation in Section 3.4.2 is a bottleneck for performance. On average 73% of the time was spent on this loop when sorting lists with uniform or normal distribution (as seen in table 4, 5). If this loop was optimised further or parallelized the performance of the sorting method could be greatly improved.

When sorting lists of exponential distribution only about 2% was on average spent on the bucket counting loop, and the percentage drops as the list size grows. This is of course because the sorting algorithm struggles to balance the work load of exponentially distributed lists, and thus sorting takes a very long time compared to sorting equally big lists of other distributions. This can be explained by the fact that an exponential distribution is close the worst case scenario for parallelised bucket sort, as most of the elements are placed in few of the buckets leaving many buckets almost empty in comparison.

To further improve performance it was attemped to fully implement pointer swapping instead of writing new values to the arrays. This did however not give the excepted result as it slowed down the program. There are some possible explanations for this, for example the program relies hevily on fetching values from arrays that are stored in order in memory. Writing new values to allocated arrays makes sure the data is stored in the relevant vicinity. Using pointer swapping will perhaps result in the memory that is pointed to being stored further apart instead, which could possibly lead to cache misses. It is also likely that the compiler generates optimised code for writing new values to memory that is more efficient than the implemented pointer swapping.

In the program there is a distinct function for choosing the pivot element for quicksort, which has been the last element in the list for all performed tests in the report. Different functions such as returning the mean or median element were also tried in order to improve performance. This did however not make the code faster and is perhaps due to the fact that the buckets are already partially sorted, meaning the range of values is reduced. Also the function that chooses the pivot element is recursively called many times, meaning a small additional computational cost could have a bigger impact than expected.

The reason the parallelization speedup does not follow the ideal speedup is because not every part of the code is able to run i parallel. Besides all the overhead for the main thread there are several spots in the code that is always run in serial, such as the bucket creation, the bucket count loop, and the cumulative sum calculation. In order to fully parallelize every part of the code, the entire process needs to be run in parallel such that each thread does bucket sort on their own subarray instead of the parallelization being inside the bucket sort. This would however mean that after merging the sorted subarrays the entire list would need to be sorted again, which would probably perform worse than the parallelisation implemented here.
